Abstract

We report the fabrication and characterisation of an organic- inorganic hybrid Photodiode (HPD) based on PCPDTBT and Zinc Oxide (ZnO) photoactive layers. The main benefit of using these materials is that multi spectral light sensing from the UV through to the Near Infrared is achieved, encompassing wavelengths ~350nm-870nm. To our knowledge, this is one of the widest range responses reported for an inorganic-organic hybrid photodiode. The evaluation of the technology shows the devices exhibit one of the lowest levels of dark currents reported for a HPD, but some limitations exist due to a low on-off ratio and non-linearity of the responsivity at low incident power. The stability of devices made with PCPDTBT:ZnO active layers is compared to more commonly reported P3HT:ZnO devices in dark and it is shown that using PCPDTBT substantially improves lifetime.

Highlights

- Wide photoresponse from UV to the NIR is achieved
- Device exhibits low dark current and high rectification ratio for a hybrid device
- Responsivity is measured and shown to be linear for incident power > 0.04W/cm²
- Improved lifetime observed with PCPDTBT active layer, when compared to P3HT-based devices

1. Introduction

Organic or hybrid photodiodes (HPDs) using metal oxide acceptor materials could have a number of advantages over the inorganic technologies, including potentially low costs, solution processability and flexibility, which could enable photodiodes to be placed onto non-flat surfaces [1,2]. Previous reports of HPDs possess a reasonable on/off ratio of photocurrent during illumination when compared to the dark current (typically >2 orders of magnitudes) [3]. Another major advantage is that the absorption profile can be 'tuned' to absorb most visible wavelengths by altering the semiconductor inside the active layer within the active layer [4].

In recent years, Zinc Oxide (ZnO) has been widely studied due to its intrinsic properties suitable for optoelectronic applications such as in hybrid devices with organic semiconductors such as solar cells and photodiodes [5]. With a wide direct bandgap of $\sim 3.4\text{eV}$ at room temperature, ZnO has been regarded as an excellent semiconductor material for UV detection and possesses an absorption profile that compliments many organic semiconductors. ZnO can be easily deposited at room- or relatively low temperatures to form thin layers by standard techniques such as sputtering [6], atomic-layer deposition [7] and pulsed-laser deposition [8]. The electron mobility is generally limited by surface roughness and carrier scatterings at grain boundaries; however, the electron mobility in ZnO has been demonstrated to reach up to $110\text{cm}^2/\text{Vs}$, when using an elevated substrate temperature during the growth step [9]. In most cases where ZnO is deposited onto substrates at room temperature, the mobility is measured to be around $1\text{-}5\text{ cm}^2/\text{Vs}$ [10]. This value still remains much higher than many organic materials which are used as the acceptor material in organic photodiodes. ZnO has also been used widely for the development of hybrid photovoltaics or photodiodes (HPDs). In photovoltaics, performances up to 0.11% have been reported for 'planar' devices, where the ZnO is deposited as a flat, uniform surface and up to 0.76% for devices made with ZnO nanowires, which create an interdigitated interface with the organic layer [11]. In addition, up to 2.0% has been reported for devices using ZnO nano-particles/crystals in a bulk-heterojunction configuration with an donor material such as Poly(3-hexylthiophene-2,5-diyl) (P3HT) [11]. Most work on hybrid devices has focused on photovoltaics and utilised organic semiconductors such as polyfluorene [12], P3HT [11] or polyaniline [13]. Whilst the performance as photovoltaics is low, the potential as photo-diodes or detectors has not been fully investigated.

In this paper, the fabrication, development and characterisation of ZnO HPDs is reported using the polymer Poly[2,6-(4,4-bis-(2-ethylhexyl)-4*H*-cyclopenta [2,1-*b*;3,4-*b'*]dithiophene)-*alt*-

4,7(2,1,3-benzothiadiazole)] (PCPDTBT). Devices are shown to possess one of the lowest levels of dark current for a HPD, though the on-off ratio is limited due to the low photoresponse of the device. However, the main benefit of using these materials to make photodiodes is that multi spectral light sensing is possible from the UV through to the Near Infrared, encompassing wavelengths $\sim 350\text{nm}$ - 870nm . To our knowledge, this is one of the widest response ranges reported for a Hybrid-photodiode. It is also one of the first reports of using a low band gap co-polymer for a hybrid device. It is shown that using PCPDTBT ensures wide photoresponse, and also enhances air stability when compared to HPDs manufactured using more commonly used materials such as P3HT.

2. Experimental

The structure of the OPD device is shown in the inset of Figure 1(a). OPD devices were initially prepared in a clean room environment using an 80nm thick indium tin oxide (ITO) coated glass substrates ($R_s = 16 \Omega/\text{square}$) that were first cleaned using deionised water, acetone and isopropanol in an ultrasonic cleaner, then treated in a UV-ozone reactor. For this work, a bilayer structure was used which is the simplest device geometry for a HPD. In this device architecture, a layer of ZnO is first deposited onto the electrode substrate, followed by the deposition of a donor organic semiconductor and finally by a top electrode.

A 25nm layer of Zinc Oxide (ZnO) was deposited using sputtering (Edwards) at a rate of $1\text{\AA}/\text{s}$ and annealed at 250°C . The donor material used was Poly[2,6-(4,4-bis-(2-ethylhexyl)-4*H*-cyclopenta [2,1-*b*;3,4-*b'*]dithiophene)-*alt*-4,7(2,1,3-benzothiadiazole)] (PCPDTBT), although in section 4, Poly-(3-hexylthiophene-2,5-diyl) (P3HT) was also used. These were prepared and mixed with chlorobenzene solvent with a concentration of 15mg/mL, with thickness of 30nm. Samples were transferred into a nitrogen atmosphere glovebox ($[\text{O}_2], [\text{H}_2\text{O}] < 1\text{ppm}$), where the donor material was applied by spin-casting (1250rpm for 60 seconds). Both the ZnO and donor material thickness was optimised. No annealing of the PCPDTBT was conducted, but P3HT was annealed at 140°C . Finally, thermal evaporation of the cathode was undertaken through a shadow mask to define the device area. This consisted of a 10 nm layer of molybdenum trioxide (MoO_3) and 200nm of silver (Ag). The corresponding energy band diagram of the device is shown in Figure 1(b). The absorption profile of the PCPDTBT and ZnO is shown in Figure 1(c).

The photoresponse studies were made with a Keithley 2600 source-measure unit (SMU) under the excitation of a Newport spectra solar simulator and a calibrated reference cell from Newport spectra. Responsivity measurements were made by illuminating the top surface of the OPD at normal

incidence. The OPD response was measured in photoconductive mode, so an external reverse bias is applied via a Keithley 2600 SMU and the current was measured using either the SMU or a lock-in amplifier with an optically chopped input signal.

3. Photodiode characterisation

Figure 2 shows the dark current and performance under $100\text{mW}/\text{cm}^2$ (AM1.5G) incident power for the fabricated PCPDTBT:ZnO HPD. The solar cell performance under AM1.5G illumination is low, with a Power Conversion Efficiency (PCE) of 0.070%. This is to be expected owing to the planar interface, which usually leads to lower performances than devices based on ZnO nanocrystals or vertically aligned ZnO nanowires, because of the smaller interfacial area between the polymer and acceptor [11]. However, this does compare closely with the 'record' efficiency for a planar HPD. Based on the data seen in Figure 2, the dark current of the PCPDTBT:ZnO HPD at 0V bias is $1.71 \times 10^{-2} \text{mA}/\text{cm}^2$ and the device exhibits an on-off ratio of ~ 150 at $100\text{mW}/\text{cm}^2$. Minimization of dark current is imperative, as this limits the minimum detectable power and also the dynamic range of the HPD, as the on/off ratio can be enhanced by reducing the dark current [15]. When compared to other HPD devices in the literature, the HPD in Figure 2 exhibits relatively low dark current [16]. The likely reason for are twofold; firstly, the overall charge transfer through the device is reduced, as a result of the low interfacial area, as previous HPDs tend to use non-planar surfaces. And secondly, the recombination of charge carriers at ITO electrode is reduced due to the larger potential barrier of the ZnO valence band (many previous reports use Titanium oxide *n*-type layers). In addition to the lower dark current, using ZnO as the acceptor material enables photocurrent generation into the UV region, giving the HPD a wider optical dynamic range. In this device, the UV response will be in practice limited by the borosilicate glass substrate, which filters out light below 340nm, but ZnO absorbs strongly below 340nm, suggesting a UV transparent substrate such as sapphire will increase the range of response of this device even further. Below 380nm, PCPDTBT does not absorb, implying that any UV part of the spectrum would be absorbed only by the ZnO layer. Figure 1(c) shows the absorption profile of both the ZnO and PCPDTBT, layers demonstrating the wide absorption properties.

To study the influence under different light intensities, we recorded J-V characteristics under different illumination power from 25 to $100\text{mW}/\text{cm}^2$. Devices were measured straight after exposure and illumination was removed in-between measurements. The responsivity of a photodiode is defined as a ratio of output photocurrent (I_{PD}) from the OPD to the incident light

power (P) from the light source, or $R(\lambda) = I_{PD} / P$. Shown in Figure 3 is the responsivity and photodiode current as a function of incident light intensity (P_{IN}) using AM1.5G illumination under -1V bias. The behaviour is linear, except at lower intensities. Below 40mW/cm², the device exhibits a decrease in I_{PD} , though for intensities greater than 40mW/cm², I_{PD} is directly proportional to incident power. This low light behaviour supports the view of other publications, which explained the effect due to electron trap saturation and limited charge transport due to the electron/hole mobility of the ZnO and PCPDTBT, respectively [17].

Overlaid on Figure 3 is the rectification ratio of the HPD as a function of incident power, obtained from plotting the diode equation under illumination and dark conditions. Under dark conditions, the rectification ratio is measured at 75 and at 100mW/cm² was measured at 46. Although the parameter is not regularly reported for HPDs, the rectification ratio at 100mW/cm² under bias of 1V is higher than many previous reports for HPDs. To obtain photodiodes with high rectification ratios, efficient charge injection through the PCPDTBT and ZnO layers under forward bias is needed. This was achieved by ensuring that the potential barriers between each layer was low, so the data supports the view that using an MoO₃ hole transport layer and Ag electrode minimises this barrier, as ITO-ZnO is already known to form an Ohmic contact [11]. The quality of the polymer film can also influence the diode properties and previous reports from this group show that the mobility of this polymer is high when using hole only devices, when compared to materials such as P3HT [18]. Rectification ratio appears to increase with reduced intensity, in agreement with other reports [16]. It has already been reported that the generation of charge carriers lowers the resistance of the bulk via a photo induced doping effect, which contributes to the increased rectification ratio as a function of input power [16].

4. Photodiode lifetime

Whilst there are many advantages to using organic or hybrid photodiodes, as listed in section 1, it is important to research the operational lifetime of the photodiodes. In Figure 4(a), the normalized photocurrent, measured at -1 V, of PCPDTBT:ZnO HPD is plotted as a function of operating hours. This device was non-encapsulated and stored in the dark in between measurements, which were conducted approximately every 24 hours. The photocurrent is relatively stable for more than 200 h, but decreases exponentially thereafter. The on/off ratio decreases approximately linearly over the first 200 hours as a result of increasing dark current. As a comparison, a P3HT:ZnO HPD is shown in figure 4 also, which displays considerably worse lifetime. This is an interesting observation; PCPDTBT

lifetime studies on photodiodes or solar cells have not been extensively reported, however, data from our laboratory suggests that PCPDTBT:PC₆₁BM based solar cells exhibit worse stability than P3HT:PC₆₁BM based solar cells.

The degradation mechanism for these types of photodiodes are numerous and complex and the difference in stability between the PCPDTBT:ZnO and P3HT:ZnO HPDs could therefore be due to a number of reasons. One likely cause is due to greater UV absorption of PCPDTBT films than in P3HT. For PCBM-based solar cells, there is limited UV cut off from PCBM material as it is blended with the polymer, however, in these HPDs, the UV will be cut off by the ZnO, so the polymer experiences low UV exposure. Therefore, PCPDTBT is less affected by UV degradation in the HPD configuration than in PCBM-based solar cells.

This could also be due to a change in polymer morphology; therefore, the surface morphology of the PCPDTBT and P3HT photodiodes were studied using an atomic-force microscope (AFM) prior to lifetime testing and after lifetime testing. Data is shown in table 1; a small difference in PCPDTBT morphology was observed, with the value of the maximum peak-to-valley fluctuation (Z_{\max}) and surface roughness (R_A) both increasing by ~25%. This compares to a much greater increase in the P3HT morphology (R_A increases by 63% and Z_{\max} by 33%).

The degradation could also be as a result of the ZnO/polymer interface due to ZnO degradation, as ZnO is also known to possess a level of instability, in particular under illumination. ZnO films naturally exhibit *n*-type conductivity and its origin has been discussed in terms of native defects, such as oxygen vacancies and zinc interstitials [20,21]. In the case of ZnO, it has been shown that oxygen vacancies in ZnO could be quenched upon chemisorbed air/oxygen exposure which reduces the carrier concentration, resulting in a field depletion of surface electrons and conduction band bending [21, 22]. This has also been reported to increase the dark current of ZnO-based HPDs, which would lead to a reduction in on-off ratios in HPDs, as a result of O₂ desorption from the ZnO [23]. This view supports the data in Figure 4(b), where on-off steadily reduces with time, primarily as a result of dark current increase. The AFM measurements in table 1 shows that the PCPDTBT active layer possesses much lower surface roughness, which suggests that the PCPDTBT molecules are slightly more densely packed, which could slow down the diffusion of oxygen and moisture to the ZnO-PCPDTBT interface. This may contribute to the improved stability for the PCPDTBT devices. As the P3HT film is more crystalline, the film possesses deeper and wider gaps at the boundaries between individual grains. Therefore, the boundaries may also be vulnerable locations for oxygen to penetrate through the film [19], leading to degradation of the ZnO interface.

5. Conclusion

In this paper we have reported a hybrid photodiode made with structure of ITO-ZnO-PCPDTBT-MoO₃-Ag. The benefit of this approach is that multi spectral light sensing is possible from the UV through to the Near Infrared, encompassing wavelengths 350nm-870nm, which is one of the widest responses observed for an organic or hybrid photodiode. A dark current at 0V bias of $1.71 \times 10^{-2} \text{ mA/cm}^2$ is observed, which leads to a low on-off ratio of ~ 180 at 100 mW/cm^2 . Devices made with PCPDTBT show good air stability, which could be further improved using encapsulation.
